## ABSTRACT

This report is the result of continued analysis of the 33 zooplankton collections made at the proposed OTEC site in the Gulf of Mexico off Tampa Bay. Six groups of zooplankton - siphonophores (Calycophora), pteropods (Thecosomata), chaetognaths, thaliaceans, euphausiids and amphipods were quantitatively investigated. Numbers and biomass were determined for all taxa and diurnal, seasonal and depth trends were discussed. Considering the present study and the previous investigation of the copepod population, this proposed OTEC site is probably one of the faunistically better known locales in the Gulf of Mexico and Caribbean.

## INTRODUCTION

In an earlier series of reports to the Lawrence Berkeley Laboratory we described the copepod fauna and general characteristics of plankton populations at the proposed OTEC site in the Gulf of Mexico off Tampa Bay. In this report we concentrate on six of the remaining groups of zooplankton, providing data on their species composition and seasonal/vertical abundance. The groups considered are siphonophores (calyphorans) pteropods (thecosomates), chaetognaths, thaliaceans, euphausiids and amphipods. While these groups in combination with the previously analyzed copepods account for the overwhelming share of plankton numbers and biomass as determined from net collections, several important groups remain to be done, e.g., larvaceans and ostracods. Even considering that taxonomic work remains incomplete, the information available from this set of OTEC samples is perhaps the most comprehensive for any single location in the Gulf and Caribbean.

This work was supported by the Assistant Secretary for Conservation and Renewable Energy, Office of Solar Power Applications, Division of Ocean Energy Systems, United States Department of Energy under contract number W-7405-ENG-48.

## METHODS

The 33 samples analyzed here were those taken on 7 cruises in 1978-79 to the proposed Gulf of Mexico OTEC site at 27.5°N, 85.5°W. These samples were previously examined for copepods and the study has been extended here to include six additional groups, calycothorax siphonophores, thecosomatous pteropods, chaetognaths, thaliaceans, euphausiids and amphipods. Because of the quantity of zooplankton in each collection it was necessary to subsample, this being done with a Motoda sample-splitting box (Motoda, 1959). In the richer collections 100 of each of the six groups were sorted into aliquots. In sparse samples all of the specimens of each group available in half the total sample were sorted, this often totalling less than 100 individuals per group. Animals were identified using both a microscope and stereo-dissecting scope, and the appropriate taxonomic literature. The major references were:

Siphonophores: Totton and Bergmann (1965); Yamaji (1972)

Pteropods: Tesch (1947); Van der Spoel (1967)

Thaliaceans: Fraser (1947); Thompson (1948)

Euphausiids: Boden, Johnson and Brinton (1955); James (1970);  
Gopalakrishnan (1975)

Amphipods: Stephensen (1918, 1924, 1925); Chevreux and Fage  
(1925); Dick (1970)

Chaetognaths: Fraser (1957); Alvarino (1969)

Maximum dimensions were measured of each identified individual and biomass was determined using length-weight regressions as described in Hopkins (1971), and Hopkins and Baird (in press). Also sex and stage

of development (i.e., adult male and female, and juveniles) were recorded for euphausiids and amphipods while siphonophore individuals were identified as anterior or posterior nectophores of either polygastric or eudoxoid life stages (see Appendix tables in a separate volume).

## RESULTS

Siphonophora (Calycophora). The most prevalent siphonophore group in the OTEC collections was the *Calycophora*. Eleven types were identified to species and these are listed in Table 1. Considering the 1000 m water column and averaging over the period of study, *Eudoxoides mitra* was the most abundant species. Other species exceeding 5% of the siphonophore numbers were *Bassia bassensis* (11.0%), *Eudoxoides spiralis* (10.0%), *Diphyes bojani* (9.8%) and *Abylopsis eschscholtzii* (8.6%). In terms of biomass *D. bojani*, *E. mitra* and *Diphyes dispar* were the top three species, constituting respectively, 19.3%, 13.2% and 8.7% of the calycophoran biomass. It should be noted that a significant fraction of the biomass (18.8%) was composed of material unidentified to species. The data on biomass may have more value than the numerical estimates because calycophoran colonies were usually fragmented in net catches and the counts here are for total individual nectophores. Counts for each type of nectophore are in the Appendix tables.

In Table 2 are the abundance data by cruise. Thirteen of the 14 categories listed were most abundant either in June, 1978 or February 1979 collections. It is uncertain, however, whether or not this represents any sort of a bimodal seasonal pattern because of the relatively small volume of water filtered on each cruise and the lack of replicates. Except for *Abyla* spp. and possibly *Abylopsis* spp., there is little evidence for diel vertical migration in this group at least in the 0-25 m layer (Table 3). Four taxa were not found in the 0-25 m zone at all (*Enneagonum hyalinum*, *Lensia fowleri*, *Lensia* spp. and *Muggiaea* spp) whereas all species were more prevalent in the epipelagic zone (0-200 m) during the day than in the deeper layers sampled (i.e., 200-800 m, 800-1000 m).

Pteropoda (Thecosomata). Twenty species of Thecosomatous pteropods were identified (Table 4), the most abundant species in the upper 1000 m being *Limacina inflata* (18.5% of total numbers of pteropods). The genus *Limacina* was, in fact, the overwhelmingly dominant category constituting 85.3% of the shelled pteropod population. The only other taxon to individually account for over 3% of the catch was *Creseis virgula* f. *virgula* (4.1%). In terms of biomass the top four categories were *Limacina* spp. (30.4%), *L. inflata* (17.4%), *Cymbulia* spp (11.6%) and *Diacria tridentata* (4.3%). Among the 20 species there appeared no consistent seasonal pattern (Table 5). Of the more common species *C. virgula* f. *virgula* had a rather uniform level of abundance from cruise to cruise whereas the other species were temporally more irregular, often being too scarce to be counted in aliquots. Diel vertical migration was apparent in some species but not others (Table 6). For example, the genus *Limacina* in general tended to be more prevalent in the upper 25 m at night than during the day. Other possible migrators were *C. virgula* f. *virgula* and *Styliola subula*, though small sample size makes this uncertain. A potential reverse migration pattern was apparent in *Cavolinia inflexa* which was more abundant in 0-25 m day collections than in night collections. All but a few species were clearly more abundant in the epipelagic zone (upper 200 m) than at depth. Only members of the genus *Clio* (*C. cuspidata* and *C. pyramida*) occurred exclusively in collections from below 200 m.

Chaetognatha. As apparent from our earlier reports based on these samples, chaetognaths constitute a significant share of the total zooplankton biomass in the upper 1000 m. The genus *Sagitta* was obviously predominant and was 96% and 86%, respectively, of the numbers and biomass of chaetognath standing crop. The principal species (Table 7) numerically were *S. enflata* (10.9%), *S. minima* (8.1%) and *S. serratodentata* (7.4%), the remaining species individually constituting less than 3% of total chaetognaths. These three species were also the major contributors to biomass (*S. enflata*: 40.3%, *S. serratodentata*: 10.7%; *S. minima*: 6.9%). Many of the smaller, immature chaetognaths, however, proved difficult to resolve taxonomically and the category of *Sagitta* spp. constituted 66% of the numbers and 21% of the biomass of this group. Diurnal patterns of abundance in the upper 25 m varied considerably from species to species (Table 8). Among the more numerous shallow dwelling species *Pterosagitta draco*, *Sagitta bipunctata*, *S. hexaptera* and *S. serratodentata* were noticeably more abundant in night than day in collections in the 0-25 m zone whereas the opposite obtained for *S. enflata* and *S. minima*. All species but two were more abundant in the epipelagic layer (0-200 m) than in the deeper zones sampled. The two exceptions, *E. fowleri* and *S. macrocephala* were taken at depths greater than 200 m. No strong seasonal patterns were obvious (Table 9), the distributions ranging from rather even from cruise to cruise (e.g., *S. serratodentata*) to occurring in samples of only one of the five cruises listed (e.g., *S. bipunctata*).

Thaliacea. The salp community at the OTEC station was not especially diverse and a significant share of the species found there (e.g., *Doliolum*) are closely related. Six species were positively identified (Table 10), the most numerous being *Thalia democratica* (32.9%) and *Salpa fusiformis* (9.8%). The most abundant thaliacean category, however, was *Doliolum* spp., (42.6% of the group), which was constituted by very small and often, damaged specimens of this genus. Identified doliolids, i.e., *D. denticulum*, *D. intermedium* and *D. gegenbauri*, ranged in abundance from 2.1 to 2.4% of the thaliacean population. In terms of biomass the above two salp species were clearly dominant, *S. fusiformis* and *T. democratica*, respectively contributing 64.7% and 12.6% of total thaliacean biomass. The principal doliolid species was *D. intermedium* which was 2.5% of total thaliacean standing crop. Again, many of the thaliaceans were small and difficult to identify, consequently 15% of the biomass remained unresolved to species.

There is evidence of diurnal vertical migration in some thaliacean species found at this station (Table 11). While not especially apparent in *S. fusiformis*, *Iasis zonaria*, *D. intermedium* and *D. gegenbauri*, night collections from the 0-25 m zone of *T. democratica* and *D. denticulatum* were much the larger. With the exception of *Salpa maxima*, all species of thaliaceans identified here were essentially epipelagic (0-200 m) in occurrence. *S. maxima* was found only in the 200-800 m zone. *Pyrosoma* colonies were relatively scarce in plankton net catches and were observed in aliquots only in the February 1979 collections. In this group, as in the others treated here, sharp seasonal trends could not be identified (Table 12).

Euphausiacea. Euphausiids rank high in the composition of zooplankton standing crop in the upper 1000 m at the OTEC site (see earlier OTEC reports). Sixteen species were identified from six genera (Table 13) and the principal species numerically were *Euphausia tenera* (11.8%), *Nematoscelis atlantica* (5.5%) and *N. microps* (5.3%). All other species were less than 4% of euphausiid numbers. In terms of biomass the principal species in the upper 1000 m were *N. atlantica* (10.7%), *E. tenera* (7.3%), *Nematobrachion boopis* (5.7%; rare but large) and *E. americana* (4.3%). The remaining species were individually less than 4% of total euphausiid standing crop. Immatures were often difficult to identify, consequently 61% of euphausiid numbers and 32% of their biomass were not resolved taxonomically to species.

Diurnal vertical movement into the upper 25 m at night was strongly reflected in data for the genus *Euphausia*, *E. tenera* and *E. americana* in particular (Table 14). *Stylocheiron* characteristically showed little movement into this shallow zone at night, with the possible exception of *S. carinatum*. Of all the groups considered here, the euphausiids demonstrated the greatest diel vertical range, this again being especially apparent in the genus *Euphausia*. Considering the available daytime data, *Euphausia*, *Nematoscelis* and *Nematobrachion* were found mostly below 200 m while the relatively non-migratory *Stylocheiron* generally remained in the epipelagic layer (with the possible exceptions of *S. elongatum* and *S. longicorne*). *Thysanopoda* were comparatively scarce. *T. monocantha* was mostly in the 0-200 m zone whereas the much rarer *T. orientalis* was restricted to collections from the intermediate 200-800 m zone. Because of sample size restrictions little can be stated on seasonality in abundance of individual species of euphausiids (see Table 15).

Euphausiaceae (Unident.)	161	33	23	15	0

Amphipoda. This group, while not conspicuously abundant, was species rich. Amphipods, however, proved difficult to identify, which was particularly the case for the immature stages. Even so, 23 species were resolved (Table 16), the most numerous being *Primno macropa* (16.7%), *Eusirus longipes* (9.5%; a gammarid), *Phronimopsis spinifera* (3.7%), *Hyperoides longipes* (2.4%), *Phronimella elongata* (1.3%), *Phrosina semilunata* (1.3%), and *phronima colleti* (1.1%). All other species individually were less than 1%. The biomass dominants were *Eusirus longipes* (34.2%), *Primno macropa* (18.8%), *Hyperoides longipes* (3.4%), *Rhabdosoma minor* (1.7%), *Phronimella elongata* (1.7%), *Parapronoe crustulum* (1.7%), and *Scina rattrayi* (1.7%). The remainder were individually less than 1% of the standing crop.

Because of their relative scarcity and the small volume of water sampled, little can be said concerning cruise-to-cruise fluctuation (Table 17). Only *Primno macropa* was found in collections from all seven cruises. Also, too few amphipods were taken to meaningfully compare day and night abundances. During the day at least, the time period for which the data are more complete, most species appear to be epipelagic, being taken primarily in the upper 200 m (Table 18).

## DISCUSSION

Species composition. All of the species listed, with the possible exception of amphipods, have previously been reported from the Gulf of Mexico, Straits of Florida or Caribbean (Moore, 1953; Lewis, 1954; Owre, 1960; Owre and Foyo, 1972; Michel and Foyo, 1976; Haagensen, 1976). The fauna at the OTEC site, then, can be considered essentially tropical-subtropical in origin. Comprehensive quantitative data such as presented here and previously (OTEC copepod data), however, are virtually unavailable for the Gulf of Mexico. The most complete data set in print wherein a wide spectrum of plankton groups has been treated is that of Michel and Foyo (1976) and Haagensen (1976) for locations in the adjacent Caribbean. As their information is not integrated over the water column nor expressed in terms of volume filtered, species quantitative and dominance patterns cannot be readily compared. Their data, as evident in ours, however, clearly indicate the quantitative importance of *Euphausia tenera*, *Thalia democratica*, *Limacina inflata* and *Sagitta enflata* within their respective groups.

Seasonal patterns. Little is known of seasonality in oceanic plankton of the Gulf of Mexico. There is some evidence for size class progressions in species of myctophids found in the eastern Gulf (Hopkins and Baird, unpublished data) and indeed, some seasonality would be predicted, at least for the shallow epipelagic fauna on the basis of Molinari and Mayer's (1980) temperature profiles. Their data show, for example, that surface temperatures can be as low as 19°C in winter (February) and exceed 29°C in the summer (August), the upper 50 m evidencing a considerable annual range. The population in the upper 1000 m of each group, expressed as numbers and biomass per square meter of sea

surface, for each cruise date, is in Figure 1. Greatest numbers for chaetognaths, pteropods, amphipods and euphausiids were for June, 1978; though pteropods were equally abundant in December 1978. Calicophoran siphonophores had had a maximum in January, 1979 and thaliaceans in April, 1979. Biomass patterns, in general, followed those of the numerical data, with the exception of pteropods. Considering the relatively small volumes of water filtered, evidence that the maxima represent seasonal patterns is uncertain at best. Similar patterns, for instance, could also be effected by major water mass replacement at the sampling site between cruises.

Another means of assessing seasonality is through analysis of size data. In figures 2 A-F are the size distributions of the six groups plotted for each cruise. There is little apparent seasonal progression in size classes of thaliaceans and calycophorans as the maximum remains in the 2-2.9 mm fraction in every cruise for the former and in the 3-3.9 mm category for the latter group. There is, however, tentative evidence for seasonality in the other groups. In chaetognaths, the 2-2.9 and 3-3.9 mm fractions are important numerically in June, 1978 collections while they contribute proportionately far less in December, 1978 and January, 1979. Euphausiids also evidenced many small (1-1.9 mm) juveniles in the population in June, 1978, whereas proportionately, markedly fewer occurred in samples from the succeeding cruises. Amphipods in general show the same pattern as euphausiids. In pteropods, the smallest size class ( $<0.3$  mm) was relatively strong in June, 1978 and August, 1978, but was less significant in the December and January collections. This size class re-appears in April, 1979 at which time it is the dominant fraction. These data only infer seasonality and more sampling at closer time intervals and over a

number of years is requisite to obtain more positive proof of seasonality in the oceanic plankton of the eastern Gulf.

Standing crop. The vertical distribution of standing crop in the upper 1000 m during the day of each of the six groups is in Figure 3. With but one exception, both numbers and biomass were concentrated in the upper 200 m. In the case of the exception, euphausiids, during the day numbers were greatest in the upper 200 m whereas biomass was concentrated more in the 200-800 m zone. This results from juvenile stages remaining in the epipelagic zone during the day and of adults and subadults, with greater biomass per individual, occupying the intermediate mesopelagic layers. As apparent from our data taken at 27°N 86°W some 48 km distant (Iverson and Hopkins, in press) from the OTEC site, standing crop, particularly in the upper 400 m, undergoes significant diel changes. In the present study the only diel comparisons available are for the 0-25 m layer. Considering only night/day differences in excess of  $\pm 30\%$  (see Table 19), calyophoran siphonophores and thaliaceans were usually more abundant in the upper 25 m during the day than at night. Chaetognaths evidenced no particular trend whereas pteropods, amphipods and euphausiids in collections from most cruises were more abundant in this zone during the night. Of these groups the euphausiids in particular are well documented as strong diel migrators (e.g., see Lewis, 1954).
